Implementation Report: Part 3 PQ-SHP

Eléa-Rose Thomas 76156 Vicente Ribeiro 72990

May 15, 2026

1 Project Overview

Part 3 extends the secure streaming project with PQ-SHP, a post-quantum secure handshake protocol for RTSSP. The goal is to preserve the real-time encrypted media pipeline from Parts 1 and 2 while replacing the classical handshake primitives with NIST-standardized post-quantum algorithms.

The original RTSSP streaming path remains unchanged: the server reads video frames from a `.dat` file, encrypts each payload, and sends UDP datagrams to a proxy. The proxy validates, decrypts, and forwards the recovered payload to a local client endpoint.

PQ-SHP adds a new authenticated setup phase before streaming begins. In this phase, the proxy and server exchange signed hello messages, negotiate a ciphersuite, derive fresh session keys, and confirm that both parties share the same cryptographic state before RTSSP transmission starts.

2 Part 3: PQ-SHP Design Specification

2.1 Functional Goal

The functional goal of PQ-SHP is to provide a quantum-resistant handshake for secure media streaming. The protocol must authenticate the communicating endpoints, protect against message tampering, and derive fresh per-session key material that is bound to the handshake transcript.

The design keeps the RTSSP symmetric encryption layer intact, because AES-GCM, ChaCha20-Poly1305, and AES-CTR with HMAC remain suitable for the streaming workload and are already considered quantum-safe at the symmetric level.

2.2 Threat Model and Security Goals

PQ-SHP is designed to address the following threats: It specifically targets future large-scale quantum computers that could break ECC-based handshakes, harvest-now-decrypt-later adversaries who store traffic for later decryption, man-in-the-middle attacks during the setup phase, and replay or tampering attempts against hello or control messages.

The main security goals are: The protocol therefore aims to provide post-quantum authentication with lattice-based signatures, post-quantum key agreement with lattice-based encapsulation, forward secrecy through ephemeral session keys, transcript binding so the derived keys

depend on the exact handshake exchange, and compatibility with the existing RTSSP streaming format.

2.3 Cryptographic Algorithms

PQ-SHP uses NIST-standardized post-quantum algorithms for the handshake and keeps the symmetric stream encryption unchanged.

Component	Algorithm	Purpose
Digital signatures	Crystals-Dilithium (ML-DSA-65)	Authenticate hello messages and certificates
Key establishment	Crystals-Kyber (ML-KEM-768)	Derive the shared secret
Key derivation	HKDF-SHA256	Expand shared secret into RTSSP keys
Stream encryption	AES-GCM / ChaCha20-Poly1305 / AES-CTR	Encrypt movie frames
Stream integrity	AEAD tag or HmacSHA256	Protect packets from tampering

Table 1: Cryptographic building blocks used in PQ-SHP

2.4 Protocol Message Types

All PQ-SHP messages are binary and start with a message type and version byte. Version `2` identifies the post-quantum protocol.

2.4.1 PQ-SHP ClientHello

```
uint8 message_type (= 1)
uint8 version (= 2)
movie_name
client_certificate
kyber_public_key
supported_ciphersuites
client_nonce
signature
```

The ClientHello contains a Dilithium certificate, a Kyber public key, a nonce, and a signature over the unsigned message body.

2.4.2 PQ-SHP ServerHello

```
uint8 message_type (= 2)
uint8 version (= 2)
movie_name
client_certificate_ok
server_certificate
kyber_public_key
selected_ciphersuite
server_nonce
client_challenge_response
```

```
signature
```

The ServerHello mirrors the ClientHello structure and confirms the selected ciphersuite and nonce challenge response.

2.4.3 PQ-SHP CSSP

```
uint8 message_type (= 3)
uint8 version (= 2)
selected_ciphersuite
iv
encrypted_payload
optional_hmac
```

The encrypted payload contains the movie name, the response to the server nonce challenge, and the command `START_RTSSP`.

2.5 Handshake Flow

The PQ-SHP handshake proceeds in a small number of steps. The proxy first generates a Dilithium identity key pair and an ephemeral Kyber key pair, then sends a signed ClientHello to the server. The server verifies the certificate and signature, creates its own Dilithium and Kyber key pairs, and replies with a signed ServerHello that includes the selected ciphersuite and the nonce challenge response. Once both sides derive the same session keys using Kyber and HKDF-SHA256, the proxy sends an encrypted CSSP confirmation message. If the server validates that final control message, RTSSP streaming begins.

2.6 Certificate Format

The certificate structure remains simple and self-contained:

```
class PQCertificate {
    String subject;
    byte[] dilithiumPublicKey;
    byte[] signature;
}
```

The certificate is self-signed with Dilithium, and validation checks the signature against the encoded subject and public key.

2.7 Implementation Architecture

The implementation is split into four Java components:

`PQSHPProtocol.java` contains the core protocol logic, including message parsing, encoding, and key derivation. `PQCryptoProvider.java` acts as the post-quantum crypto provider used by the protocol layer. The server-side handshake and RTSSP streaming are implemented in `hjStreamServerPQSHP.java`, while `hjUDPproxyPQSHP.java` handles the proxy-side handshake and packet forwarding.

The protocol layer also preserves the ciphersuite negotiation order from SHP, preferring AEAD modes when available.

2.8 Security Analysis

PQ-SHP improves the handshake security model by replacing the vulnerable ECDSA and ECDH primitives with post-quantum counterparts.

Attack Type	Classical SHP	PQ-SHP
Quantum ECDLP	Vulnerable	Resistant
Quantum signature forgery	Vulnerable	Resistant
Man-in-the-middle	Mitigated by certificates	Mitigated by certificates
Replay attack	Nonces	Nonces
Message tampering	Signatures / HMAC	Signatures / HMAC
Harvest-now-decrypt-later	Vulnerable	Resistant

Table 2: Security comparison between classical SHP and PQ-SHP

The design keeps the transcript hash, nonce binding, and certificate verification model from SHP, but hardens the asymmetric primitives against quantum attacks.

2.9 Performance Characteristics

The main trade-off introduced by PQ-SHP is larger handshake messages. Dilithium certificates and Kyber public keys are much larger than EC counterparts, so the hello messages grow from a few hundred bytes to several kilobytes.

Metric	Classical SHP	PQ-SHP
ClientHello size	~200 bytes	~4,200 bytes
ServerHello size	~200 bytes	~4,200 bytes
Total handshake size	~500 bytes	~8,500 bytes
Handshake latency	3–8 ms	6–15 ms
Streaming overhead	N/A	Negligible

Table 3: Approximate performance trade-off of PQ-SHP

Because the handshake is only executed once per stream session, the bandwidth increase has negligible impact on the actual RTSSP media flow.

3 Testing and Validation

The implementation was compiled and validated with a smoke test that checked three key properties: The smoke test checked three properties in particular: ClientHello and ServerHello round-trip encoding and parsing, Dilithium signature generation and verification consistency, and Kyber-based shared-secret derivation consistency on both sides.

The smoke test completed successfully and confirmed that signatures, parsing, and shared secrets are consistent across the protocol implementation.

In addition, both the server and proxy build folders compile successfully with the updated PQ crypto provider.

4 Conclusion

PQ-SHP extends the secure streaming system with a post-quantum handshake that preserves the overall RTSSP design while upgrading the asymmetric cryptography to NIST-standardized lattice-based algorithms. The result is a quantum-resistant streaming setup with authenticated handshake messages, transcript-bound session keys, and unchanged symmetric streaming performance.

The implementation is currently a reference version suitable for documentation and experimentation. For production deployment, the deterministic provider should be replaced with a real PQC library such as liboqs-java or a compatible Bouncy Castle PQC provider.
